High Levels of Dopamine D2 Receptors in Unaffected Members of Alcoholic Families

Possible Protective Factors

Nora D. Volkow, MD; Gene-Jack Wang, MD; Henri Begleiter, MD, PhD; Bernice Porjesz, PhD; Joanna S. Fowler, PhD; Frank Telang, MD; Christopher Wong, MS; Yeming Ma, PhD; Jean Logan, PhD; Rita Goldstein, PhD; David Alexoff, BSE; Peter K. Thanos, PhD

Context: Predisposition to alcoholism is likely an interaction between genetic and environmental factors that confer vulnerability and protection. Alcoholic subjects have low levels of dopamine D2 receptors in striatum, and increasing D2 receptor levels in laboratory animals reduces alcohol consumption.

Objectives: To test whether high levels of D2 receptors may be protective against alcoholism and whether this is mediated by their modulation of activity in orbitofrontal cortex and cingulate gyrus (regions involved in salience attribution, emotional reactivity, and inhibitory control).

Design: Research (nonalcoholic subjects with a family history of alcoholism) and comparison (nonalcoholic subjects with a negative family history) sample.

Setting: Outpatient setting.

Participants: Fifteen nonalcoholic subjects who had an alcoholic father and at least 2 other first- or second-degree relatives who were alcoholics (family-positive group) and 16 nonalcoholic controls with no family history of alcoholism (family-negative group).

Main Outcome Measures: Results of positron emission tomography with raclopride C 11 to assess D2 receptors and with fludeoxyglucose F 18 to assess brain glucose metabolism (marker of brain function). Personality measures were obtained with the Multidimensional Personality Questionnaire.

Results: Availability of D2 receptors was significantly higher in caudate and ventral striatum in family-positive than family-negative subjects. In family-positive but not family-negative subjects, striatal D2 receptors were associated with metabolism in anterior cingulate (Brod mann area 24/25) and orbitofrontal (Brodmann area 11) and prefrontal (Brodmann area 9/10) cortices, and with personality scores of positive emotionality.

Conclusions: The higher-than-normal D2 receptor availability in nonalcoholic members of alcoholic families supports the hypothesis that high levels of D2 receptors may protect against alcoholism. The significant associations between D2 receptors and metabolism in frontal regions involved with emotional reactivity and executive control suggest that high levels of D2 receptors could protect against alcoholism by regulating circuits involved in inhibiting behavioral responses and in controlling emotions.

Arch Gen Psychiatry. 2006;63:999-1008

GENETIC FACTORS HAVE A powerful influence on alcoholism, accounting for approximately 50% to 60% of the population variance. Genetic associations are both direct (ie, via genes that regulate alcohol's metabolism and its reinforcing or aversive effects) and indirect (ie, via genes that affect personality characteristics and externalizing disorders). However, it is also evident that environmental factors as well as gene-environment interactions play a crucial role in vulnerability and in protection against alcoholism. Several neurotransmitters appear to mediate alcohol's reinforcing and addictive effects (ie, γ-aminobutyric acid [GABA], dopamine [DA], opioids, serotonin, and N-methyl-D-aspartate). Of these, DA is believed to play an important role in alcohol's reinforcing effects. The DA D2 receptor is one of the DA receptor subtypes involved in transmitting these reinforcing signals. This fact has been documented in a variety of ways; for example, D2 receptor antagonist drugs decrease reinforcing responses to alcohol in rodents and in humans. Also, studies have shown differences in D2 receptor levels be-
between rat strains that differ in their preferences for alcohol, and D_2 receptor knockout mice exhibit reduced reinforcing responses to alcohol. In humans, imaging studies have shown that differences in D_2 receptor availability in nonalcoholic subjects are associated with differences in sensitivity to the intoxicating effects of alcohol. Levels of D_2 receptor may also be involved with alcohol addiction, as evidenced by imaging and postmortem studies showing reductions in D_2 receptor levels in the striatum from the brains of alcoholic subjects. Because low D_2 receptor availability in striatum has also been documented in other drug addictions when compared with non–drug-abusing control subjects, it has been postulated that this reduction may render an individual more vulnerable to substance abuse. However, an alternative explanation could be that the higher levels of D_2 receptor in striatum observed in non–drug-abusing controls could reflect a protective effect against substance abuse in these subjects. This hypothesis is supported by imaging studies showing that controls with high D_2 receptor availability in striatum report aversive responses to stimulant drugs. Also, preclinical studies show that overexpression of D_2 receptor in nucleus accumbens markedly reduces alcohol intake, even in selectively bred alcohol-prefering P rats.

Herein we test the hypothesis that high D_2 receptor availability may be protective against alcohol abuse. We reasoned that the population of individuals who, despite a dense positive family history of alcoholism (biological father and at least 2 other first- or second-degree relatives), are not alcoholic may be enriched with protective factors, including high D_2 receptor availability. Therefore, we selected subjects who met these criteria for our study. Of course, this reasoning also suggests that the population of individuals with a positive family history and who are alcoholic themselves may lack protective factors, but we did not select this group as a comparison because long-term alcohol use can alter striatal D_2 receptor expression, which would interfere with the identification of variables that protect against alcoholism.

Positron emission tomographic (PET) imaging with carbon 11 (^{11}C)-labeled raclopride was used to measure D_2 receptor availability. In addition, we used fludeoxyglucose F 18 (FDG) to measure regional brain glucose metabolism (marker of brain function), since we also hypothesized that protection is mediated by D_2 receptor modulation of the activity in the orbitofrontal cortex (OFC) and anterior cingulate gyrus (CG), which are brain regions involved with salience attribution and inhibitory control. Indeed, in addicted subjects, lower-than-average D_2 receptor availability is associated with lower-than-average metabolism in OFC and CG (reviewed by Volkow et al), and in alcoholic subjects, low metabolism in these regions persists after protracted detoxification and may underlie vulnerability to relapse. We also used the Multidimensional Personality Questionnaire to investigate whether a D_2 receptor protective effect is associated with personality characteristics that decrease the likelihood of alcohol abuse (positive emotionality).

**METHODS**

**SUBJECTS**

Family-positive (FP) subjects were 15 individuals (1 woman and 14 men; mean ± SD age, 24 ± 3 years) who had an alcoholic biological father (according to DSM-IV) with an early-onset history of alcoholism (before 25 years of age) and at least 2 other first- or second-degree relatives who were or had been alcoholics. Subjects were excluded if they had a previous or current history of abuse of or dependence on alcohol and/or other drugs of abuse (except nicotine), or any other DSM-IV Axis I diagnosis of mental illness and/or neurologic illnesses in themselves or in a first-degree relative (except for a family history of alcoholism), or if they had medical illnesses and/or were taking any prescribed medications. Nondrinkers (consuming alcohol less than once every year) were also excluded because we wanted to exclude subjects who may have not become alcoholics because they had minimal or no exposure to alcohol. Family-negative (FN) subjects were 16 controls (2 women and 14 men, aged 26 ± 4 years). Subjects were excluded if they had a family history of alcoholism or drug abuse in first- and/or second-degree relatives. Otherwise, criteria were as for FP subjects.

As part of the evaluation procedure, subjects underwent physical, psychiatric, and neurologic examinations. A standardized interview was used to ensure that subjects fulfilled the inclusion and exclusion criteria. Routine laboratory tests were performed, as was a random urine test to exclude the use of psychoactive drugs. Subjects were instructed to discontinue any over-the-counter medication 2 weeks before the PET scan and to refrain from drinking alcohol the week before the PET scan. Cigarettes, food, and beverages (except for water) were discontinued at least 4 hours before the study. This study was approved by the institutional review board at Brookhaven National Laboratory. After the procedure was explained, written informed consent was obtained from each subject.

**PERSONALITY MEASURES**

Participants completed the Multidimensional Personality Questionnaire. The personality measures were scored for the 3 superfactors of positive emotionality (or extraversion), negative emotionality (neuroticism), and constraint. Positive emotionality is a combination of scores for the scales of well-being, social potency, achievement (including motivation), and social closeness. Negative emotionality is a combination of scores for the scales of stress reaction, alienation, and aggression. The constraint factor is a combination of scores for the scales of self-control, harm avoidance, and traditionalism.

**PET STUDIES**

The PET studies were carried out with an HR+ tomograph (resolution, 4.5 × 4.5 × 4.5-mm full-width at half-maximum, 63 sections; Siemens Medical Solutions, Knoxville, Tenn) in a 3-dimensional dynamic acquisition mode. Subjects underwent scanning with [^{11}C]raclopride and with FDG. Methods for positioning of subjects, catheterizations, transmission scans, and blood sampling and analysis have been published for [^{11}C]raclopride and for FDG. Briefly, for [^{11}C] raclopride, emission scans were started immediately after injection of 4 to 8 mCi (148-296 MBq) (specific activity was 0.5-1.5 Ci/μmol [1.85-5.59 × 10^10 Bq/μmol] at the end of bombardment), and a total of 20 emission images were obtained from the time of injection up to 54 minutes. Arterial sampling was used to measure total carbon 11 and unchanged radiotracer in plasma. For FDG, a 20-minute emission scan was started 35 minutes after injec-
tion of 4 to 6 mCi (148-222 MBq) of FDG, and arterialized blood was used to measure FDG in plasma. Metabolic rates were computed by means of an extension of Sokoloff’s model. The emission data for all of the scans were corrected for attenuation and reconstructed with filtered back projection.

IMAGE ANALYSIS AND STATISTICS

For region identification for the [11C]raclopride images, the time frames from dynamic images taken from 10 to 54 minutes were summed, and the summed image was resectioned along the intercommissural plane (anterior commissure-posterior commissure line). Planes were added in groups of 2 to obtain 12 planes encompassing the caudate, putamen, ventral striatum, and cerebellum for region-of-interest (ROI) placement. The caudate, putamen, ventral striatum, and cerebellum were measured on 4, 3, 1, and 2 planes, respectively, and right and left regions were averaged. These regions were then projected to the dynamic scans to obtain concentrations of carbon 11 vs time. These time-activity curves for tissue concentration were used to calculate distribution volume ratios in caudate, putamen, and ventral striatum by means of a graphical analysis technique for reversible systems. The distribution volume ratio, which is the ratio of the distribution volume (DV) in striatum to that in cerebellum and which corresponds to \( \frac{\Omega_2}{B_{max}K_d} + 1 \) (where \( \Omega_2 \) indicates free fraction in the first tissue compartment, \( B_{max} \) receptor concentration; and \( K_d \), affinity), was used as an estimate of \( D_2 \) receptor availability. Differences in \( D_2 \) receptor between FP and FN subjects were tested with unpaired t tests.

The metabolic images were analyzed by statistical parametric mapping (SPM). For this purpose, the images were spatially normalized by means of the template provided in the SPM 99 package (Statistical Parametric Mapping, Cambridge, England), then normalized to the mean metabolic activity for the whole brain (mean of all voxels within the brain) and subsequently smoothed with a 16-mm isotropic gaussian kernel. Independent (unpaired) t tests were used to compare the images between FP and FN subjects. We hypothesized, on the basis of our previous findings, that FP subjects would have decreases between FP and FN subjects. We hypothesized, on the basis of coordinates in the Talairach Daemon software (1) into the normalized FDG PET image. This automated ROI extraction method was based on the standard brain template of the Talairach atlas. First, to eliminate variations across individuals’ brains, the FDG images were mapped into the Montreal Neurological Institute standard brain space by means of the spatial normalization package provided in SPM. To perform the ROI calculations, we produced a map that covered the 3 factor scores (positive emotionality, negative emotionality, and constraint) and \( D_2 \) receptor availability in caudate, putamen, and ventral striatum. To assess the correlations between personality measures and regional metabolism, we determined Pearson r values between the 3 factor scores and the metabolic measures (for each voxel by SPM). The statistically significant r values were overlaid on a magnetic resonance imaging structural image. The significant correlations were then corroborated by means of the independently drawn ROI.

In consideration of the “multiple comparison problem,” we set the level of significance for a priori hypotheses to \( P<.05 \): (1) increases in FP subjects in \( D_2 \) receptor availability in striatum; (2) correlations between \( D_2 \) receptor availability and metabolism in OFC, CG, and prefrontal cortex; (3) correlations between \( D_2 \) receptor availability and personality measures of positive emotionality; and (4) decreases in FP subjects in baseline cerebellar and hippocampal metabolism. For the exploratory analyses, significance was set to \( P<.005 \) (corrected for multiple comparisons; clusters \( \geq 100 \) voxels) and corroborated with independently drawn ROI.

RESULTS

DEMOGRAPHICS AND PERSONALITY MEASURES

There were no differences in age, sex, education, socioeconomic status, ethnicity, smoking histories, verbal IQ, or scores on the Beck Depression Inventory between the 2 groups of subjects (Table 1). The comparison of the personality measures, which were completed by 13 FP and 11 FN subjects, showed significant differences between the groups. The scores for positive emotionality were lower in FP than in FN subjects (46.8±10 vs 56.3±8; \( P=.02 \)) and, within this factor, showed lower scores on the well-being (6.9±3 vs 9.7±1; \( P=.007 \)) and the achievement (12.4±4 vs 16.4±2; \( P=.006 \)) scales. The scores on the constraint factor did not differ between FP and FN subjects (44.0±14 vs 32.8±9; \( P=.10 \)) but showed a trend toward lower scores on the self-control scale in FP subjects (13.4±5 vs 17.7±5; \( P=.06 \)). Scores on negative emotionality did not differ between groups.

D2 RECEPTOR AVAILABILITY IN FP AND FN SUBJECTS

Analysis of the [11C]raclopride images showed no group differences in \( K_1 \) measures (transport constant of radiotracer from plasma to tissue) in striatum or in cerebellum (Table 2). In contrast, the measures of D2 receptor availability differed significantly between groups (Figure 1). The FP subjects had significantly higher measures of D2 receptor availability in caudate (\( P = .02 \)) and in ventral striatum (\( P = .02 \)) than the FN subjects (Table 2).

To assess whether nicotine affected D2 receptor availability, we also looked for differences between smokers and nonsmokers and found no differences for any of the striatal regions (data not shown).

REGIONAL BRAIN METABOLISM IN FP AND FN SUBJECTS

Comparison by SPM at \( P < .05 \) (“a priori hypothesis”) showed that FP subjects had lower metabolism in hippocampal gyrus and cerebellum than FN subjects (Figure 2). It also showed lower metabolism in temporal pole (Brodmann area [BA] 20) and higher metabolism in prefrontal cortex (BA 8, 9, 10) in FP than FN subjects. However, these differences were not significant for the SPM comparison at \( P < .005 \) (“exploratory analysis”).

CORRELATIONS BETWEEN D2 RECEPTOR AVAILABILITY AND REGIONAL BRAIN METABOLISM

The pattern of correlations obtained between regional brain metabolism and striatal D2 receptor with SPM (voxel level) was similar for the striatal regions (caudate, putamen, and ventral striatum). Thus, we averaged the D2 receptor measures in the striatal regions to show the results for the correlations. The SPM performed at a significance level of \( P < .05 \) to test the a priori hypothesis.

Figure 1. Images for the distribution volume ratios of carbon 11 (\(^{11}\text{C}\))–labeled raclopride showing higher dopamine D2 receptor availability in a family-positive than in a family-negative subject. Images shown correspond to levels where the striatum and cerebellum are visualized.

Figure 2. Statistical parametric mapping images showing regions where metabolism was higher in family-positive than in family-negative subjects (orange) and where metabolism was lower in family-positive than in family-negative subjects (blue) (\( P < .05 \), corrected, cluster size >100 voxels). BA indicates Brodmann area.
showed significant positive associations for the FP subjects between metabolism and striatal D2 receptor in frontal cortical regions (including prefrontal cortex, anterior CG, and OFC) (Figure 3A). The SPM performed at a significance level of $P < .005$ for the exploratory analysis showed that the only significant correlation was with medial BA 11 (Figure 3B). These correlations were corroborated with ROI, which showed a positive correlation between striatal D2 receptor and metabolism in OFC (BA 11) ($r = 0.85; P < .001$), ventral CG (BA 24/25) ($r = 0.66; P < .008$), and prefrontal cortex (BA 9/10) ($r = 0.72; P < .003$) (Figure 3C, Table 3). For the FN group the correlations with D2 receptor were not significant.

CORRELATIONS BETWEEN REGIONAL BRAIN METABOLISM AND PERSONALITY MEASURES

The SPM performed at a significance level of $P < .005$ for the exploratory analysis showed that the correlations were significant for FP but not FN subjects. In FP subjects, scores on positive emotionality were significantly correlated with metabolism in left OFC (BA 11) ($r = 0.85; P < .001$), ventral cingulate gyrus (BA 24/25) ($r = 0.66; P < .008$), and prefrontal cortex (BA 9/10) ($r = 0.72; P < .003$) (Figure 4A). For the FN group the correlations with D2 receptor were not significant.

COMMENT

D2 RECEPTOR DIFFERENCES BETWEEN GROUPS

The significantly higher D2 receptor availability in caudate and in ventral striatum in the FP group compared with the FN group corroborates our working hypothesis that a high D2 receptor level in striatum is a protective factor against alcohol abuse. This assumes that, despite a family history of alcoholism, nonalcoholic members of alcoholic families may be enriched with protective factors, including high D2 receptor availability, that comp...
pensate for the higher inherited vulnerability. These results are in agreement with those reported by a PET study of siblings discordant for cocaine abuse that showed not only that the cocaine-abusing sibling had a lower D2 receptor level than a control group but also that the nonabusing sibling had a higher D2 receptor level than the control group.

In the present study, it was not possible to determine whether high D2 receptor availability in FP nonalcoholic subjects reflects underlying genetic or environmental factors or their interactions. There is evidence that genetic as well as environmental factors are involved in D2 receptor expression. Moreover, in nonhuman primates, it has been shown that when social environmental factors result in high D2 receptor levels, this is associated with protection, and when they result in low D2 receptor levels, this is associated with a propensity to self-administer cocaine. However, high D2 receptor availability could also reflect a genetic modulation toward favorable responses to social stressors (ie, growing up in a household with an alcoholic parent).

In previous studies, we showed that in non–drug-abusing subjects D2 receptor availability was associated with the reinforcing responses to the psychostimulant drug methylphenidate hydrochloride; subjects with low D2 receptor availability tended to report an acute intravenous administration of methylphenidate as pleasant, whereas those with high D2 receptor levels tended to report it as unpleasant. Also, a recent study documented that subjects with high D2 receptor availability showed higher levels of intoxication after alcohol than subjects with low D2 receptor levels, who showed blunted responses. Inasmuch as subjects with blunted responses to alcohol have been shown to have a higher risk of alcoholism, the latter study is also consistent with the hypothesis that high D2 receptor availability may be protective. Moreover, preclinical studies have shown that in rodents trained to self-administer alcohol, D2 receptor overexpression in nucleus accumbens markedly reduces alcohol intake both in rats that are genetically predisposed to self-administer alcohol (alcohol-preferring rats) and in those that are not (Sprague-Dawley); this finding provides evidence that high D2 receptor availability may interfere with alcohol intake, even in animals that are genetically prone to administering alcohol.

Further evidence of the involvement of D2 receptor in alcohol preferences is given by findings of lower D2 receptor levels in alcohol-preferring rats than in alcohol-nonpreferring rats, and of increases in alcohol intake after microinjection of a D2 receptor antagonist into the nucleus accumbens in alcohol-preferring rats. Also,

Figure 4. Correlations between regional brain metabolism and positive emotionality. Statistical parametric mapping images for the family-positive subjects showing areas where metabolism was significantly correlated with scores on positive emotionality (P<.005, corrected; cluster size, >100 voxels).
D2 receptor antagonists increase alcohol relapse rates in alcoholic subjects. Thus, the current findings and those from the preclinical literature are compatible with the notion that D2 receptor modulates the motivation to self-administer alcohol.

The D2 receptor gene (in particular, the Taq1 A1 polymorphism) has been one of the most widely investigated and one of the most controversial in alcoholism. Also controversial is the extent to which the Taq1 A1 polymorphism affects the expression of D2 receptor in the brain. In the present study, we document an increase in D2 receptor availability in unaffected FP individuals rather than a decrease, which is what is reported for alcoholics. This suggests that it is unlikely that genetically determined low expression of D2 receptor underlies the inherited vulnerability to alcoholism but rather that low D2 receptor levels in alcoholic subjects reflect a gene-environment interaction (including long-term alcohol abuse), while the increased D2 receptor availability in nonalcoholic subjects provides a protective factor as they go through the age of risk.

REGIONAL BRAIN METABOLIC MEASURES

The SPM replicated our previous findings of reduced baseline cerebellar metabolism in FP subjects. In that study we also reported that a group of FP subjects showed a blunted cerebellar response to the benzodiazepine drug lorazepam, which led us to postulate that the cerebellar findings in this group could reflect differences in GABAergic benzodiazepine receptors. The hippocampal gyrus, which in the present study was also found to have reduced metabolism in the FP subjects, is a brain region that similarly contains a high density of GABAergic receptors. Thus, these findings are compatible with recent genetic studies reporting an association between alcoholism and the GABAergic receptor gene.

RELATIONSHIP BETWEEN D2 RECEPTOR AND METABOLISM IN OFC, CG, AND PREFRONTAL CORTEX

The significant association between D2 receptor levels and metabolic measures in OFC and CG in FP subjects is similar to what we had previously reported in cocaine- and methamphetamine-addicted subjects in whom higher levels of D2 receptor were associated with higher metabolic activity in OFC and anterior CG. Because the OFC and CG are involved with inhibitory control, we had postulated that the improper regulation by DA of these regions in addicted subjects could underlie their loss of control and compulsive drug intake. Indeed, in alcoholic subjects reductions in D2 receptor availability in ventral striatum have been shown to be associated with alcohol craving severity and with greater cue-induced activation of the medial prefrontal cortex and anterior CG as assessed with functional magnetic resonance imaging. The observed association between D2 receptor and OFC and anterior CG confirmed our hypothesis that the effects of D2 receptor on vulnerability to addiction may be mediated by activity in brain regions that control inhibitory and emotional responses.

In addition, we showed in FP subjects an association between D2 receptor and activity in prefrontal cortex (BA 9/10). Imaging studies have consistently shown an involvement of the prefrontal cortex in emotional processing. It is postulated that emotional information from limbic regions is conveyed to the prefrontal cortex, where conscious and voluntary emotional self-regulation occurs. Indeed, activation of the prefrontal cortex and of ventral CG (BA 24/25) has been documented with conscious suppression of sexual arousal and of sadness. Thus, enhanced dopaminergic signaling through D2 receptor could protect against alcoholism by favoring control over emotional reactions.

The association between striatal D2 receptors and metabolism in OFC, CG, and prefrontal cortex could reflect either striatal modulation of frontal regions via striatothalamocortical projections or frontal modulation of striatal regions by glutamatergic frontomesencephalic and frontostriatal projections. Most of the D2 receptor-containing neurons in striatum are GABAergic, and DA signals in striatum are transferred to cortical regions via GABAergic pathways, which are inhibitory. Because a factor that has been associated with inherited vulnerability to alcoholism is impairment in inhibitory neurotransmission, high D2 receptor levels could exert a protective effect by increasing modulation of GABA cells and thus compensating for this deficit.

RELATIONSHIP BETWEEN D2 RECEPTOR, REGIONAL BRAIN METABOLISM, AND PERSONALITY MEASURES

It is likely that the inherited vulnerability to alcoholism is not specific to this drug. Instead, it has been postulated that what is inherited are personality characteristics (eg, novelty seeking, disinhibition) that are associated with alcohol abuse. In this study, the FP group had lower scores than the FN group in measures of positive emotionality and showed a trend toward a decrease in the scores of self-control. Because individuals scoring low on positive emotionality have higher thresholds for the experience of positive emotions and for positive engagement with their social environment, one could postulate that this could put them at risk for alcohol abuse as a means to compensate for this deficit. Indeed, a common expectation for alcohol's effects is facilitating interpersonal closeness and the pleasure from social interactions.

The positive emotionality measures were also correlated with activity in left BA 11. Because D2 receptor availability in striatum was also associated with metabolism in BA 11, this could be a neurobiological substrate through which DA via D2 receptor could modulate positive emotional responses and protect against alcohol abuse. In addition, the association of D2 receptor with dorsolateral frontal cortex could also protect by favoring cognitive control over emotional responses.

LIMITATIONS

In this study we show that unaffected members of families with a history of alcoholism may have a protective factor, namely, high D2 receptor availability. However,
we cannot rule out the possibility that the FP subjects were not alcoholics because they did not inherit the vulnerability genes.

This study reports a 10% difference in the availability of D₂ receptor between FP and FN subjects. Even though this may seem like a modest difference, it is equivalent to what we have reported between subjects who show pleasant vs aversive responses to the stimulant drug methylenedate.22 Also, in studies of normal aging, we have shown that a 10% difference in D₂ receptor is associated with 12% difference in locomotor speed,68 suggesting that a 10% D₂ receptor difference is functionally significant.

We interpret the increases in D₂ receptor availability as reflecting increases in the levels of receptors. However, because [11C]raclopride is sensitive to competition with endogenous DA, we cannot rule out the possibility that FP subjects could have decreases in DA release that result in high D₂ receptor availability. This interpretation is less likely, since endogenous DA is estimated to occupy, under baseline conditions, 10% of D₂ receptors,68 which is equivalent in magnitude to the difference observed between the FP and the FN groups. This would mean that FN subjects would have to have double the baseline levels of endogenous DA of FP subjects, ie, levels equivalent to those reported in schizophrenic subjects in whom these high DA levels are associated with psychoses.65 However, we cannot rule out the possibility that the inherited vulnerability is a decrease in baseline DA for which FP subjects compensate by up-regulating D₂ receptor.

The correlation between D₂ receptor and OFC and CG metabolism was observed in FP but not FN subjects, and whereas D₂ receptor levels are higher in FP than FN subjects, metabolism in OFC and CG is not. It would therefore appear that, in FP subjects, high D₂ receptor availability is required to maintain metabolic levels in OFC and CG comparable to those in FN subjects. Thus, we cannot rule out the possibility that the high D₂ receptor availability in FP subjects may reflect a compensation for a primary deficit in OFC and CG.

The mean age of the FP group was 24 years. An examination of the data from the Collaborative Study on the Genetics of Alcoholism, which consists of a large sample of densely affected alcohol-dependent families, showed that when offspring of probands who meet DSM-IV criteria for alcohol reach 24 years of age, 83.5% of those who will develop alcohol dependence have already done so (Bernice Porjesz, PhD, Henri Begleiter, MD, Laura Bierut, MD, unpublished data, 2006). Thus, it is plausible that 15% to 20% of the FP subjects could still become alcoholics. Also, these results do not imply that high D₂ receptor levels in these subjects will protect them for the rest of their lives; D₂ receptor levels in brain are sensitive to social stressors and drug exposure (reviewed by Nader and Czoty65) and thus are likely to change differently throughout the life span of individuals. Prospective studies will enable us to determine whether non-alcoholic FP subjects will become alcoholics later in life and to evaluate whether this is associated with a reduction in D₂ receptor levels.

Finally, in this study we did not exclude smokers. However, the facts that the 2 groups did not differ in the percentage of smokers and there were no differences in D₂ receptor levels between smokers and nonsmokers suggest that nicotine does not drive the findings.

### CONCLUSIONS

The finding of high D₂ receptor availability in subjects who are not alcoholic, despite risk of alcoholism due to family history, supports the hypothesis that high D₂ receptor levels exert a protective effect against alcoholism. The positive association between D₂ receptor availability and metabolism in OFC, CG, and prefrontal cortex, which are regions involved with inhibitory control, emotional reactivity, and executive function, as well as with personality measures of positive emotionality, suggests that cognitive and emotional processes may be mechanisms underlying the protective effects of high D₂ receptor levels.

**REFERENCES**

Errors in Table and Figure. In the Original Article by Giesen-Bloo et al titled “Outpatient Psychotherapy for Borderline Personality Disorder: Randomized Trial of Schema-Focused Therapy vs Transference-Focused Psychotherapy,” published in the June issue of the ARCHIVES (2006;63:649-658), there were several errors in Table 1. The table is reprinted correctly as follows. Furthermore, neither recent suicide planning, steps, or attempts nor recent nonsuicidal self-injury were significantly related to recovery from borderline personality disorder or changed the difference between schema-focused therapy and transference-focused psychotherapy when these variables were entered alone or in combination in the survival analyses. In all analyses, schema-focused therapy remained superior to transference-focused psychotherapy. Treatment group by suicidal or self-injury manifestation interaction was not significant. In addition, the x-axis label in the survival analyses. In all analyses, schema-focused therapy remained superior to transference-focused psychotherapy.
