Treatment of Atypical Depression With Cognitive Therapy or Phenelzine

A Double-blind, Placebo-Controlled Trial

Robin B. Jarrett, PhD; Martin Schaffer, MD; Donald McIntire, PhD; Amy Witt-Browder, MA; Dolores Kraft, PhD; Richard C. Risser, MS

Background: Patients with atypical depression are more likely to respond to monoamine oxidase inhibitors than to tricyclic antidepressants. They are frequently offered psychotherapy in the absence of controlled tests. There are no prospective, randomized, controlled trials, to our knowledge, of psychotherapy for atypical depression or of cognitive therapy compared with a monoamine oxidase inhibitor. Since there is only 1 placebo-controlled trial of cognitive therapy, this trial fills a gap in the literature on psychotherapy for depression.

Methods: Outpatients with DSM-III-R major depressive disorder and atypical features (N = 108) were treated in a 10-week, double-blind, randomized, controlled trial comparing acute-phase cognitive therapy or clinical management plus either phenelzine sulfate or placebo. Atypical features were defined as reactive mood plus at least 2 additional symptoms: hypersonmia, hyperphagia, leaden paralysis, or lifetime sensitivity to rejection.

Results: With the use of an intention-to-treat strategy, the response rates (21-item Hamilton Rating Scale for Depression score, $\leq 9$) were significantly greater after cognitive therapy (58%) and phenelzine (58%) than after pill placebo (28%). Phenelzine and cognitive therapy also reduced symptoms significantly more than placebo according to contrasts after a repeated-measures analysis of covariance and random regression with the use of the blind evaluator's final Hamilton Rating Scale for Depression score. The scores between cognitive therapy and phenelzine did not differ significantly. Supplemental analyses of other symptom severity measures confirm the finding.

Conclusions: Cognitive therapy may offer an effective alternative to standard acute-phase treatment with a monoamine oxidase inhibitor for outpatients with major depressive disorder and atypical features.

Arch Gen Psychiatry. 1999;56:431-437

Patients with major depressive disorder (MDD) and atypical features have shown a preferential response to phenelzine sulfate compared with imipramine hydrochloride in placebo-controlled trials,\(^1\)\(^-\)\(^7\) prompting the recommendation of monoamine oxidase inhibitors (MAOIs) as the standard of care.\(^8\) Unfortunately, MAOIs have dietary restrictions, contraindications, and well-known side effects.\(^3\)\(^-\)\(^5\) Although Reimherr et al\(^10\) and Pande et al\(^11\) showed that fluoxetine hydrochloride may offer an alternative, many patients cannot or will not take antidepressant medication. Since psychosocial treatments are sought by and prescribed for depressed patients with atypical features, studies of efficacy and effectiveness are needed.

Cognitive therapy is effective for some patients with MDD.\(^12\)\(^-\)\(^13\) Mercier and colleagues\(^14\) showed that cognitive therapy reduced symptoms of depressed outpatients with atypical features. In depressed outpatients who were not subtyped, acute-phase cognitive therapy is more effective than waiting-list controls,\(^15\) has not differed significantly from antidepressant medication used alone,\(^12\)\(^-\)\(^16\) and may not differ when combined with pharmacotherapy.\(^12\)\(^-\)\(^19\)\(^,\)\(^20\)

We defined atypical features as a subtype of MDD during which patients have reactive mood and at least 2 of the following 4 symptoms: hyperphagia, hypersonmia, leaden paralysis, or a lifetime history of interpersonal sensitivity to rejection, resulting in functional impairment. This definition is comparable with that used in DSM-IV\(^21\) and has heuristic value in selecting patients who respond to phenelzine.

The purpose of this double-blind, placebo-controlled trial of outpatients with MDD and atypical features was to compare acute-phase cognitive therapy with the standard of care, phenelzine. Phenelzine was selected instead of a selective serotonin reuptake inhibitor because there is more support for its efficacy in this patient population.\(^1\)\(^-\)\(^7\) We hypothesized that cognitive therapy and phenelzine would each reduce depressive symptoms signifi-
PATIENTS AND METHODS

PATIENTS

The protocol was approved by the institutional review board. Subjects (recruited through media, printed announcements, and self or practitioner referrals) underwent triage by telephone. Outpatients (N = 366) with the complaint of depression participated in the Structured Clinical Interview for DSM-III-R (Outpatient Version), which uses the DSM-III-R criteria for MDD and other disorders. To assess MDD with atypical features, the Atypical Depression Diagnostic Scale (Jonathan W. Stewart, MD, written communication, October 20, 1988, and March 20, 1990) was administered for the initial episode. If the diagnosis was absent at the nadir, symptoms were reassessed at “any other time during the episode.” Criteria (according to the Atypical Depression Diagnostic Scale) for depression with atypical features included (1) maintains reactive mood and (2) shows 2 or more of the following: (a) increased appetite or weight gain; (b) over-sleeping; (c) sensation of leaden paralysis or extreme heaviness of arms or legs, while depressed; and (d) lifetime sensitivity to interpersonal rejection.

Diagnoses were confirmed by a faculty-level diagnostician at a follow-up interview. Entry criteria were (1) DSM-III-R MDD, (2) definite atypical depression, and (3) score of 14 or more on the 21-item Hamilton Rating Scale for Depression (HRSD-21) at the initial or follow-up interview. All patients provided a medical history and a physician reviewed laboratory screening.

Patients were excluded if they (1) had a concurrent medical disorder or treatment that might cause depressive symptoms or required medication incompatible with MAOIs; (2) refused to be randomized or to maintain a tyramine-free diet; (3) had other current primary comorbid psychiatric disorders (eg, organic mental disorders, psychotic disorders, schizophrenia, schizoaffective disorders, alcoholism, or drug abuse or dependency in the last 6 months); (4) scored less than 14 on the HRSD-21 at diagnostic evaluation and follow-up, or before randomization (see description of nonspecific treatment below); (5) could not complete questionnaires; (6) represented an imminent suicide risk; or (7) had previously had an adequate trial of MAOIs or cognitive therapy that failed.

RESULTS

SAMPLE DESCRIPTION

One hundred forty-two outpatient with MDD and atypical features consented to participate in the trial. The subjects who were eligible and ineligible for randomization did not differ significantly on the variables in Table 1.

Attrition

Thirty-six patients were randomized to each cell. Attrition differed significantly among the treatment cells (χ² = 22.04; P ≤ .001). Five patients (14%) dropped out of cognitive therapy, 9 (25%) from phenelzine, and 23 (64%) from placebo. Attrition in the placebo group was significantly greater than in cognitive therapy (χ² = 18.94; P = .001) and phenelzine (χ² = 11.03; P = .001). The attrition between active treatments did not differ significantly (χ² = 1.42; P = .23). Of patients in cognitive therapy, 1 dropped out before the first session, 2 moved, and 2 found the study procedures unacceptable.

Nine patients randomized to phenelzine did not complete the trial. Of these, the psychiatrist withdrew 3 whose depressive symptoms required alternative treatment. Six dropped out. One dropped out after the first session, 3 found the treatment unacceptable, and 2 found the study unacceptable.

Of the 366 patients studied, 287 (78.4%) were diagnosed as having MDD; of the patients with MDD, 242 (66.1% of those studied) were also diagnosed as having atypical depression. One hundred eighty-one (49.5%) were eligible. Thirty-nine (21.3%) refused consent (generally because of scheduling problems or the desire to receive or avoid a study treatment). The nonspecific treatment baseline (designed to identify and exclude patients who respond to early, nonspecific effects) was initiated when patients signed consent (n = 142). Subjects participated in 2 sessions (during 14 days) of nonspecific treatment by watching a videotape on mood disorders and reporting on symptoms from the HRSD-21. At the end of nonspecific treatment, 13 patients had responded (ie, HRSD-21 < 14 or no MDD) and were referred.

Final eligibility for randomization was evaluated by confirming that the inclusion criteria were met. One hundred eight (76.0% of the consenting and eligible) patients were randomized (Table 1) under the supervision of the statistician (D.M.), who kept research personnel blind to assignment (phenelzine or placebo) during the study.

TREATMENT PROCEDURES

Cognitive Therapy

Cognitive therapy was conducted as described by Beck et al29 for 10 weeks, in 20 individual sessions held twice weekly. Three experienced male therapists provided cognitive therapy. Two were doctoral-level clinical psychologists and 1 was a psychiatrist. An offsite consultant (see acknowledgments) used the Cognitive Therapy Scale to evaluate competence and provide feedback to therapists and investigators.

Therapists participated in weekly group supervision. Of 64 total Cognitive Therapy Scale ratings (ie, 2 planned per patient), 9 (14%) received scores of less than 40. The grand mean Cognitive Therapy Scale score across all therapists was 46.1 ± 4.1. The analyses of variance showed no statistically significant differences in the mean Cognitive Therapy Scale scores among therapists (F1.2 = 2.50; P = .09) or across years (F1.40 = 1.40; P = .24).

Phenelzine and Placebo

A treatment manual modeled after the National Institute of Mental Health Treatment of Depression Collaborative
Twenty-three patients randomized to placebo did not complete the trial. The psychiatrist withdrew 4 because their symptoms necessitated alternative treatment and 2 because they were noncompliant with study procedures. Of the 17 patients who withdrew their consent, 2 dropped out before the first session, 14 found the treatment unacceptable, and 2 because their symptoms necessitated alternative treatment and 2 because they were noncompliant with study procedures. Of the 17 patients who withdrew their consent, 2 dropped out before the first session, 14 found the treatment unacceptable, and 2

**Treatment Exposure**

Patients treated with cognitive therapy completed an average of 17.4 ± 0.9 sessions (range, 0-20) during an average of 8.8 ± 0.5 weeks (range, 0-11.1). Patients treated with phenelzine completed an average of 9.8 ± 0.4 sessions (range, 1-11) during an average of 8.8 ± 0.5 weeks (range, 0-10.6). Patients treated with placebo completed an average of 6.9 ± 0.6 sessions (range, 0-11) during an average of 5.9 ± 0.6 weeks (range, 0-10.3).

**PRIMARY OUTCOME MEASURES AND ANALYSES**

The raw data collected for each group at baseline and at blind evaluations (weeks 4, 7, and 10) were reduced to unadjusted means and SEs for the HRSD-21, Clinical Global Impression Scale, and Beck Depression Inventory (Table 2).

**Covariate Selection**

Randomization did not achieve complete pretreatment equivalence among cells. Length of illness, Research Diagnostic Criteria primary depression, age at onset, and

---

**STATISTICAL ANALYSES**

The hypothesized response rates were 33% for placebo and 64% for both phenelzine and cognitive therapy. The primary dependent variable (identified a priori) was the HRSD-21 score collected at week 10 by an evaluator blind to treatment assignment. Randomization was restricted by stratification. Strata included length of current episode (≤2 years vs >2 years) and marital status at the time of the initial diagnostic evaluation (cohabiting or married vs living without a partner [single, divorced, separated, or widowed]).

Analysis of covariance (ANCOVA) was selected a priori as the primary statistical analysis. A repeated-measures ANCOVA with 3 treatments (cognitive therapy, phenelzine, and placebo) by 3 times (blind evaluation at weeks 4, 7, and 10) was conducted, where the covariates were age at onset and HRSD-21 at randomization. When attrition occurred, the end point was carried forward.

Within secondary analyses, a random coefficients regression (RCR) analysis was used to complement the ANCOVA, because it accommodates attrition of subjects over time by using available data without carrying over end points. The primary parameters estimated by RCR are overall slopes for each treatment supplemented by tests of differences among the slopes. Inclusion of covariates in the RCR models was evaluated by means of backward elimination with a P < .10 criterion for retention.

All analyses were of an intention-to-treat strategy (ie, using the 108 patients randomized). Discrete variables were reported as percentage of frequency (eg, number and percentage), while continuous variables were reported with a mean ± SE. An α level of P = .05 was used to define significance. Fisher exact tests were 2-tailed, while χ² tests, analyses of variance, ANCOVAs, and RCR analyses were 1-tailed.
HRSD-21 score at randomization were identified as possible covariates.

The mean duration of illness (years) for the cognitive therapy cell was significantly greater than for phenelzine, but did not differ from that of the placebo cell. The mean duration of illness for the placebo cell did not differ from that of the phenelzine cell. A rate of Relzine, but did not differ from that of the placebo cell. There was no difference in primary depression between the phenelzine and placebo cells. The phenelzine cell had the greatest age at onset, and the cognitive therapy cell had the lowest age at onset, while the placebo cell fell in the middle. These cells did not differ significantly. Finally, post hoc comparisons on the HRSD-21 at randomization disclosed no significant differences. All other comparisons among treatments on the variables in Table 1 did not differ significantly.

Because of intercorrelations among the 4 potential covariates, backward elimination was used to select statistically important covariates. Variables that remained significant (P < .10) were age at onset and HRSD-21 score, which were included as covariates in tests of the primary hypothesis.

Repeated-Measures ANCOVA of HRSD-21

With ANCOVA, the main effects for time and treatment were significant (F2,103 = 27.5; P ≤ .001 and F2,103 = 6.83; P < .01, respectively). The interaction between treatment and time was not significant (F2,103 = 1.12; P = .35). The contrasts for the main effects indicate significant differences when comparing phenelzine with placebo (F1,103 = 11.90; P < .001) and cognitive therapy with placebo (F1,103 = 7.73; P < .01). There was no significant difference between phenelzine and cognitive therapy (F1,103 = 0.37; P = .54). Post hoc pairwise contrasts of the treatment cells showed that at week 4, phenelzine reduced the adjusted mean HRSD-21 scores (13.36 ± 1.06) more than placebo (17.20 ± 1.05) (F1,103 = 6.66; P < .01). At weeks 7 and 10, both cognitive therapy and phenelzine reduced the adjusted mean HRSD-21 score over that of placebo (week 7: F1,103 = 7.29; P < .01 [cognitive therapy vs placebo]; F1,103 = 12.60; P < .001 [phenelzine vs placebo]; week 10: F1,103 = 8.94; P < .01 [cognitive therapy vs placebo].

*Double depression is defined as the presence of dysthymia before the onset of the current episode.
**Lifetime comorbidity reflects 2 or more DSM-III-R Axis I disorders occurring during the lifetime.
placebo]; F\textsubscript{1,103} = 9.30; P < .01 [phenelzine vs placebo]). Week 7 adjusted HRSD-21 means were 10.92 ± 1.11 for cognitive therapy, 9.63 ± 1.11 for phenelzine, and 15.14 ± 1.09 for placebo. Week 10 adjusted HRSD-21 means were 9.42 ± 1.22 for cognitive therapy, 9.36 ± 1.22 for phenelzine, and 14.56 ± 1.20 for placebo. The HRSD-21 score from week 0 was included as one of the covariates in the adjusted-mean HRSD-21 score for each treatment at weeks 4, 7, and 10 (Figure 1).

SECONDARY OUTCOME MEASURES AND ANALYSES

Response Rates

Most definitions of positive response rates for the active treatments (which used end points from each measure and were unadjusted for the influence of the covariates)

were greater than 50% (Table 3). Analyses by χ² showed significant differences in response rates when positive response was defined at blind evaluation as follows: HRSD-21 score of 9 or less (χ²\textsubscript{2} = 8.98; P = .01), Clinical Global Impression Scale score of 2 or less (χ²\textsubscript{2} = 10.67; P < .01), and no MDD with an HRSD-21 score of 9 or less (χ²\textsubscript{2} = 7.45; P = .02). Post hoc comparisons on these definitions of response showed that cognitive therapy and phenelzine produced higher response rates than placebo, and that cognitive therapy and phenelzine did not differ. With the use of traditional α levels, response rates did not differ between the 3 groups when a positive response was defined as an HRSD-21 score of 6 or less (χ²\textsubscript{2} = 5.93; P = .03) and no MDD (χ²\textsubscript{2} = 4.43; P = .11).

Random Regression Modeling

In the RCR analysis, only the HRSD-21 score at randomization was retained through the backward elimination steps. To linearize change in HRSD-21 scores over the 10 weeks, the time scale was transformed by using the natural logarithm of day of randomization +1; thus, slope estimates approximate change in HRSD-21 score per unit change in the log of day after baseline. Significantly different slopes over

![Figure 1. Analysis of covariance of 21-item Hamilton Rating Scale for Depression from the blind evaluator for weeks 4, 7, and 10. At week 10 the active treatments reduced symptoms significantly more than placebo (phenelzine sulfate [F\textsubscript{1,103} = 9.30; P < .01] and cognitive therapy [F\textsubscript{1,103} = 8.94; P < .01], where 36 patients were randomized to each group).](image)
time were found among the 3 treatments (treatment × time interaction, $F_{2,161} = 4.25; P < .02$). There is a significantly larger negative slope for the phenelzine cell ($F_{1,161} = 7.56; P < .01$) compared with placebo, and for the larger cognitive therapy slope compared with placebo ($F_{1,161} = 5.29; P < .03$). The slopes for the 2 active treatments did not differ significantly ($F_{1,161} = 0.23; P = .63$). Slopes estimates (per natural logarithm of day in treatment) for the 3 treatments (with SEs) are $-0.78 \pm 0.33$ for placebo, $-1.83 \pm 0.31$ for cognitive therapy, and $-2.03 \pm 0.31$ for phenelzine. The estimated time course of HRSD-21 scores for each of the 3 cells across the 10 weeks of acute-phase treatment was based on a subject with an average baseline HRSD-21 score of 17.5 (Figure 2).

**Adverse Effects**

There were no serious or persistent adverse events. From 38 potential side effects, 23 symptoms were reported by 3 or more patients and rated by the psychiatrist as “due to the study” and “moderate.” Incidence density ratios (ie, [frequency of symptoms with phenelzine/treatment weeks]/[frequency of symptoms with placebo/treatment weeks]) were computed. Weakness or fatigue, drowsiness or sedation, insomnia, dry mouth, dizziness, and increased appetite were significantly more likely to be reported by patients treated with phenelzine than those treated with placebo ($\chi^2$ test; $P < .01$, Bonferroni correction). More patients treated with phenelzine reported marked side effects (33/36 [92%]) than did patients treated with placebo (19/36 [53%]).

**COMMENT**

The results of this placebo-controlled, randomized trial indicate that both cognitive therapy and phenelzine are effective treatments for patients with MDD and atypical features. Effects of cognitive therapy and phenelzine were comparable on all outcome measures.

The implication is that cognitive therapy is an effective acute-phase alternative to MAOIs for patients with MDD and atypical depression. This trial has design features relevant to evaluating the efficacy of cognitive therapy and phenelzine for depression. It is only the second randomized trial of cognitive therapy, to our knowledge, to include a pill placebo plus clinical management. The first was the National Institute of Mental Health Treatment of Depression Collaborative Research Program. Both studies used an evaluator blind to treatment assignment to assess efficacy, which is infrequent in studies of cognitive therapy. In both studies, therapists were monitored longitudinally. Unlike the National Institute of Mental Health collaborative study, in this study (1) supervision occurred weekly in a group format and was not limited to occasions when competency fell below a set criterion and (2) patients received cognitive therapy twice a week during 10 weeks. This study is also the first independent, prospective replication, to our knowledge, that phenelzine reduces symptoms of MDD and atypical features more than pill placebo. In the current trial, MAOI levels after administration of phenelzine documented the adequacy of the standard treatment comparison.

The trial has limitations. First, although attrition in this trial was comparable with that of others, it was significantly greater for patients treated with placebo than with cognitive therapy or phenelzine. This attrition was largely initiated by the patients, reflecting their right to withdraw, and the ineffectiveness and unacceptability of placebo relative to well-publicized effective alternatives. Random regression analysis and analyses of covariance produced comparable results, suggesting that the differential efficacy of the active treatments relative to placebo in this intent-to-treat sample was not caused by a carryover bias. Second, the generalizability of the findings requires investigation. The patients represent those who were willing to undergo randomization. The modal patient was a white woman approaching midlife with a moderate level of depression and atypical features. The cognitive therapists were experienced, and weekly supervision likely maintained their adherence and competence. The psychopharmacologist was similarly experienced and used MAOI levels to aid dosing. To produce greater levels of response, remission, and recovery, both practicing cognitive therapists and psychopharmacologists might increase the frequency of cognitive therapy sessions or the dose of phenelzine and would likely increase the duration of treatment. We are conducting a follow-up pilot study to examine how the patients who responded to each treatment fared during 24 months when treatments were continued or discontinued for 8 more months. Results from the acute phase suggest that cognitive therapy is comparable with pharmacotherapy (ie, more than half of the patients who begin respond). If these findings are replicated, patients with atypical depression will benefit from greater choices. These findings highlight the potential significance of additional randomized controlled trials to evaluate the efficacy of other promising short-term psychotherapies (eg, interpersonal psychotherapy, marital therapy, and behavior therapy), compared with standard pharmacotherapy for patients with atypical depression.

In conclusion, the results of this randomized controlled clinical trial suggest that cognitive therapy, when
