Background: Tics are involuntary, brief, stereotyped motor and vocal behaviors often associated with irresistible urges. They are a defining symptom of the classic neuropsychiatric disorder, Tourette syndrome (TS), and constitute an example of disordered human volition. The neural correlates of tics are not well understood and have not been imaged selectively.

Methods: Event-related $[^{15}O]H_2O$ positron emission tomography techniques combined with time-synchronized audio and videotaping were used to determine the duration of, frequency of, and radiotracer input during tics in each of 72 scans from 6 patients with TS. This permitted a voxel-by-voxel correlational analysis within Statistical Parametric Mapping of patterns of neural activity associated with the tics.

Results: Brain regions in which activity was significantly correlated with tic occurrence in the group included medial and lateral premotor cortices, anterior cingulate cortex, dorsolateral-rostral prefrontal cortex, inferior parietal cortex, putamen, and caudate, as well as primary motor cortex, the Broca’s area, superior temporal gyrus, insula, and claustrum. In an individual patient with prominent coprolalia, such vocal tics were associated with activity in prerolandic and postrolandic language regions, insula, caudate, thalamus, and cerebellum, while activity in sensorimotor cortex was noted with motor tics.

Conclusions: Aberrant activity in the interrelated sensorimotor, language, executive, and paralimbic circuits identified in this study may account for the initiation and execution of diverse motor and vocal behaviors that characterize tics in TS, as well as for the urges that often accompany them.

Arch Gen Psychiatry. 2000;57:741-748

Tourette syndrome (TS) is a classic neuropsychiatric disorder characterized by multiple motor and vocal tics. Tourette syndrome is seen worldwide, with typical onset in childhood, and a prevalence of approximately 5 per 10000. Comorbid obsessive-compulsive, attention-deficit, and learning disorder features have been described as well. There is a significant genetic component in TS, with a suggestion of autosomal dominant transmission, although there have been no significant linkage findings to date. Autoimmune mechanisms have also been implicated in some cases.

SUBJECTS AND METHODS

SUBJECTS AND CLINICAL CHARACTERIZATION

Six right-handed male patients with a DSM-IV diagnosis of TS (mean age, 36.7 years; range, 25-47 years; duration of illness: mean±SD, 30.3±10.9 years) and frequent tics were studied after informed consent was obtained. Two patients were unmedicated and 4 suffered from tics despite neuroleptic medication (chlorpromazine dose equivalents, 2175, 50, 300, and 75 mg). All patients were assessed with the Yale Global Tic Severity Scale (mean±SD score, 39.3±12.2 of 55), the questionnaire form of the Leyton Obsessional Inventory (mean±SD score, 23.0±15.9 of 68), and the Beck Depression Inventory (mean±SD score, 7.2±6.0 of 39). Patients with notable head or neck tics, which could produce substantial head movement, were excluded. During the study sessions, all patients had simple and complex motor tics in varying muscle group distributions. Five patients had simple vocal tics, 4 of them had complex vocal tics, including coprolalia in 3.

SCAN CONDITIONS

Each of the patients was scanned 12 times, once every 10 minutes. Before each of the scans in the study session, each patient was instructed to relax, to close his eyes, and to allow the tics to emerge if they happened to occur, without any effort to induce or suppress them. The motor tics were monitored with 2 video cameras: 1 focusing just on the face and 1 covering the entire body. The vocal tics were monitored with a throat microphone and tape recorder, as well as with the video/audio camera. The video and audio tapes were time-synchronized with the computer that logged the whole-brain time-activity curve, which reflects radiotracer delivery to the brain during each scan. Head motion was kept to less than the full-width half maximum of the smoothed spatial resolution of the images with a custom-designed head holder that provided comfortable restraint.

IMAGE ACQUISITION, PROCESSING, AND STATISTICAL ANALYSIS

Regional cerebral blood flow was measured (as an index of neuronal activity) with a Siemens 935B PET scanner (Siemens Medical Systems, Hoffman Estates, Ill) in high-sensitivity 3-dimensional mode using a low-dose (15-mCi) [15O]H2O slow-holus technique, with 90-second acquisition (including a critical period of approximately 30 seconds, during which the pattern of radiotracer distribution in the brain is determined). The procedure was covered under an approval by the local hospital ethical committee and the Administration of Radioactive Substances Advisory Committee, United Kingdom. The data were corrected for background activity and attenuation, reconstructed (Hanning filter 0.5; 8.4-mm resolution full width half maximum), and the images were realigned to one another, smoothed with a 15×15×15-mm gaussian filter, transformed to the stereotactic space of Talairach and Tournoux, and normalized using an analysis of covariance to remove the effect of differences in global blood flow across scans or sessions. For each of the 12 scans in the study session, the type and distribution of each tic, and the timing and duration of each tic in relation to radiotracer delivery was noted on video and audio tapes. This information was obtained by a neuropsychiatrist (K.-Y.C.) extremely experienced with tics and TS patients, who repeatedly watched and listened to the tapes (which had time markers) to determine the tic information for each second of the critical radiotracer delivery periods. This information was then used to derive a weighted score for each scan, reflecting the contribution of radiotracer deposition during tics to the images. There was a spread of scan scores over the study session, reflecting differences across scans in the exact timing, duration, and frequency of tics, as well as the dynamic nature of the radiotracer input function during each scan. An event-related count correlation analysis was then performed within the framework of voxel-by-voxel Statistical Parametric Mapping. Without the need for separate “nontic control scans,” this symptom-specific analysis identifies voxels with intensities covarying with the scores, corresponding to areas of the brain in which activity is specifically associated with the tics. The group analysis was performed for all 72 scans by determining the significance of the average covariate (tic scan score) effect, or average correlation, at each voxel, in a linear model (multiple regression with block effect), including subject-specific parameters for the scan scores, an effect for global cerebral blood flow, and additive subject effects; the latter adjust for between-subject differences in mean regional cerebral blood flow not accounted for by global changes. The effect of neuroleptic medication was minimized within subjects by focusing exclusively on the variance induced by tics (present despite medication in the medicated subjects) within a study session in which the dose was constant; it was minimized across subjects by the removal of subject-specific effects (which included medication dose), and by considering chlorpromazine equivalent doses as covariates of no interest. A similar, single-subject analysis was performed with data from an individual patient, for whom separate coprolalia/vocal tic and motor tic scores were calculated for each of 12 scans in the study session.

tics lethargica. The dopaminergic system has been implicated in TS because dopaminergic medication can induce tics, while blockade of dopaminergic neurotransmission can be effective in their suppression. Most in vivo radioligand imaging and postmortem histochemical studies of TS have therefore focused on presynaptic and postsynaptic dopaminergic function in the basal ganglia, although a number of other brain regions and neurochemical (including peptide and second messenger) systems have been examined. Recent structural magnetic resonance imaging studies have demonstrated abnormalities of volume and lack of normal asymmetry in the basal ganglia. A possible role for the anterior cingulate and midbrain in the generation of tics has also been suggested. Single-photon emission computed tomography and fludeoxyglucose F 18 positron emission tomography (PET) studies in the “resting” baseline state have produced variable results, with decreased or increased activity described in regions such as the striatum and thalamus, and premotor, sensorimotor, and paralimbic cortices. Disordered interactions between subcortical, paralimbic, and sensorimotor brain regions have also been
postulated. A recent functional magnetic resonance imaging study focusing on the suppression of tics found that increased severity of tics outside the scanner was associated with less of a suppression-related decrease in ventral globus pallidus, putamen, and midthalamus activity (and less of a corresponding increase in midfrontal, lateral temporal, inferior occipital, and head of caudate activity).

To date, the functional neuroimaging experiments of TS have provided extremely valuable information, but have not measured (or, in some cases, controlled for) tic occurrence during scanning, and therefore have not generated an image of the brain state specifically associated with tics. We have developed and validated methods of PET image acquisition and analysis that can isolate patterns of brain activity associated with transient, randomly occurring neuropsychiatric states. These methods have been used to study the functional neuroanatomy of hallucinations (involuntary perception) in schizophrenia.

In this study, they were used to examine the pathophysiology of tics (unvoluntary/uninvoluntary action) in TS.

**RESULTS**

The group results were assessed at a threshold of $P<.005$, with spatial extent of activations corrected for multiple comparisons at a threshold of $P<.05$. Increased brain activity highly correlated with tic behavior was detected in a set of neocortical, paralimbic, and subcortical regions, including supplementary motor, premotor, anterior cingulate, dorsolateral-rostral prefrontal, and primary motor cortices, the Broca’s area, insula, claustrum, putamen, and caudate. Activations in superior temporal gyrus, inferior parietal cortex, and a point near the anterior thalamus, extending toward the head of caudate were also detected. These foci of activation are displayed and characterized in Figure 1 and Table 2.

For a single subject in whom greater than 90% of vocal tics were coprolalia, separate scan scores were generated for coprolalia/vocal tics and for motor tics. At a threshold of $P<.005$, with spatial extent corrected for multiple comparisons at $P<.05$, coprolalia was associated with activity in a set of regions, including the frontal operculum and the Broca’s area (Brodman areas [BAs] 44, 45 ($z=4.34$; $x, y, z=−30, 20, 16$) (extending ventrally in the opercular region adjacent to BA 47; $z=2.88$; $x, y, z=22, 28, 0$); superior temporal gyrus ($BA 42; z=4.22; x, y, z=−56, 26, 16$); head of caudate ($z=3.46; x, y, z=−4, 10, 12$); body of caudate ($z=2.72; x, y, z=12, 6, 20$) (BA 22; $z=4.05$; $x, y, z=−50, −40, 12$); and somatosensory cortex (BA 2; $z=4.36$; $x, y, z=34, −40, 4$)). While the sensorimotor activations were on the left at this threshold, right-sided activations, as well as putamen activation, were seen at a lower threshold ($P<.01$, uncorrected) in this subject. It should be noted that, although the distribution differed, vocal tics occurred simultaneously with a subset of the motor tics in this subject, so one would not expect that these activations represent maps purely of vocal or motor tics. It should also be kept in mind that certain regions of activation may become apparent with the increased power of the group analysis, while other regions may be more specific to an individual analysis.

**COMMENT**

These results define a distributed neural system in which abnormal activity is associated with the spontaneous initiation of, or failure to suppress, motor and vocal behavioral repertoires in this group of TS patients. Prominent activity was noted in primary motor and Broca’s areas, corresponding to the modality-specific outflow pathways of behavioral expression in motor and vocal tics. Striatal activity was also noted, supporting the involvement of basal ganglia circuits that are emphasized in traditional pathophysiological models of TS. The extensive activity in executive and premotor regions may be particularly notable, and may help to extend our understanding of disordered action and volition in TS, because these regions have traditionally been associated with the selection, preparation, and initiation of behavior.

Activity detected in the striatum can be seen in the context of cortico-striato-pallido-thalamo-cortical circuits that modulate activity in parallel brain systems underlying discrete psychomotor functions with specific functional and somatotopic organization. Within these circuits, the direct and indirect basal ganglia pathways provide a balance of excitation and inhibition that may
be disrupted in TS. A failure of inhibition in motor cortex of TS patients, due to subcortical afferent disinhibition and/or to failure of intracortical inhibition, has been suggested by a transcranial magnetic stimulation study. The findings of the current study implicate 3 of the cortico-striato-pallido-thalamo-cortical circuits in particular: the motor, dorsolateral prefrontal, and anterior cingulate circuits. These circuits are involved in the selection, programming, initiation, and control of movement. Dopaminergic projections from the midbrain tegmentum, a region where activation was noted at a threshold of $P < .005$ (uncorrected), are involved in the modulation of these circuits. This modulation may provide a mechanism of symptom formation (excess dopamine) and treatment effect (dopamine blockade) in TS.

For particular tics, the specific cortical and subcortical regions that are activated may determine the phenomenology of the behavior. In the individual analysis, coprolalia (which comprised more than 90% of the vocal tics) was associated with activation in the region of the Broca's area and the frontal operculum, known to be involved in the generation of speech. Activation was also noted in the head of the caudate, which has recently been identified by lesion methods as a critical component of the network underlying language. The other language regions noted (including posterior superior temporal gyrus, middle temporal gyrus, and supramarginal gyrus) may have been involved in the generation or the subsequent hearing of the self-generated linguistic material. Activation in the posterior conglute gyrus has recently been described in association with emotional linguistic material. The thalamic and cerebellar activations are consistent with the roles of these structures in modulating outflow of the cortical-subcortical circuits implicated. In contrast to the vocal tics, motor tics were associated with notable sensorimotor cortex activation. It is likely that activations of somatotopically specific subregions in sensorimotor cortices would be associated with movements in specific corresponding muscle groups.

Activity in anterior cingulate, premotor, and supplementary motor areas, and dorsolateral prefrontal cortex, detected in the current study, has been described in tasks involving conscious, volitional behavior, and is thought to be involved in the selection, preparation, and initiation of action. Activity in the supplementary motor area has also been noted in the performance of over-

Figure 1. Stereotactic axial sections of brain areas with significantly increased activity during tics (motor and vocal) in 6 patients with Tourette syndrome. Functional positron emission tomography results (thresholded at $P < .005$, with spatial extent corrected for multiple comparisons at a threshold of $P < .05$) are displayed in color, superimposed on a single structural T1-weighted magnetic resonance imaging scan that has been transformed into the stereotactic coordinate space of Talairach and Tournoix (for anatomical reference). Section numbers refer to the distance (in millimeters) from the anterior commissure-posterior commissure line, with positive numbers being superior to the line. The areas of maximal activation are described in the text and listed in Table 1.
learned (automatic) motor sequences.33 Activation of medial premotor association cortices has been associated with self-generated movements and activation of lateral premotor association cortices has been associated with externally cued voluntary movements.33 The striking activation of both medial and lateral premotor systems in this study suggests that both systems can be implicated in “unvoluntary” internally generated action. The involvement of the lateral premotor system may reflect the response to internal sensations, which are now known to be a common component of tics in TS.53,54 One study has reported a lack of normal premovement potentials associated with simple tics,52 while another study found that premotor potentials were present during tics in some patients.53 In either event, tics may differ from externally cued, planned movement in the timing, sequence, coherence, or distribution of premotor activity, and complex tics might be expected to involve more premotor activity than simple tics. A study of electroencephalographic microstates suggested differences between TS patients and normal subjects during simple and complex movements.56 While the purpose of this study was to characterize the functional neuroanatomy of tics, future comparisons of tics vs volitional movements in TS patients, and of volitional movements in TS patients vs normal subjects, may help to clarify these issues.

The lesion and stimulation literature is also relevant to the interpretation of the findings in this study. Lesions or failure of activation of the medial frontal premotor system, prominently activated in this study, have been associated with the inability to initiate voluntary action.50,51 Conversely, stimulation of, or seizure activity in, these regions can produce complex vocal and motor automatisms (sometimes associated with urges and emotions) resembling tics. This is particularly the case with the anterior cingulate, which is part of the rostral limbic system, and integrates affective cues with executive functions for the selection of context-dependent behavior.23,62 The prominently activated insula is also involved in the integration of internal motivational states, with behavior appropriate for the extrapersonal world (entailing behavioral triggering or inhibition functions), in the imparting of affective tone to experience and behavior, and in somatosensory, linguistic, and self-generated motor functions.63 Like the cingulate, it performs these roles by serving as a convergence point with widespread multimodal, limbic, and basal ganglia connections.63 Dysfunction (including abnormal gating) in these phylogenetically older paralimbic regions may contribute to the primitive, uninhibited behavior of TS. The maxima of some of the activations in the insular region were centered on the claustrum. While such a small localization must be considered with caution, it is worth noting that the claustrum has connectivity with sensorimotor, premotor, and anterior cingulate regions, and is involved in the performance of movements.64-66

The predominantly dorsal location of anterior cingulate activation, rostral location of supplementary motor activation,67 and dorsolateral location of prefrontal activation associated with tics in this study represents intermittent increased activity of executive components of the motor system (although supplementary motor cortex overall is considered premotor, and the cingulate also contains direct corticospinal projections23). Executive dysfunction has been noted in neuropsychological tests of patients with TS.68,69 Tonic overactivity of frontal executive systems, coupled with hypoactivity in primary sensorimotor cortices, has been implicated in idiopathic dystonia, characterized by involuntary motor posturing and slowing.70 Increased activity in orbitofrontal cortex and anterior cingulate cortex, and their subcortical connections (including the head of the caudate), has been implicated in obsessive-compulsive symptomatology,71 characterized by involuntary thoughts and complex actions, and seen with increased frequency in patients with TS.5 Given the differential prefrontal projections to various regions of the striatum (premotor to putamen and prefrontal to head of caudate), it might be expected that putamen dysfunction would be associated with a greater degree of motor symptomatology, whereas caudate dysfunction would be associated with a greater degree of cognitive symptomatology.72

The results of this “state” study of tics in TS may also be seen in the context of prior “trait” studies50-51 of TS. When the variable results of the previous trait studies are taken together, they suggest a tonic dysregulation of a number of the regions in which increased activity was detected in this symptom-state examination.

*Coordinates in millimeters relative to the anterior commissure: x is the lateral distance from the midline (positive = right); y, the anteroposterior distance from the anterior commissure (positive = anterior); and z, the height relative to the intercommissural line.
†Indicates the maximum coordinate in a brain region adjacent to a gray matter structure that is part of the same contiguous activation.*
The decreased activity noted in some of the previous studies may reflect inhibition of tics during those study sessions (such inhibition is unlikely in the current study, as patients were reminded not to suppress tics before each scan and had frequent tics during each scan, with which brain activity was directly correlated). It is also possible that tonic decreased activity alternates with intermittent increased activity during tics in the regions implicated in TS. Although tics are not frank seizures, such a temporal pattern would be similar to that described in PET studies of epileptic foci, and consistent with an imbalance of excitation and inhibition.

The results of this study may help to expand the interpretation of the results of a previous functional magnetic resonance imaging study that examined tic suppression in TS. That study compared a condition in which tics were suppressed with a condition in which tics were expressed. The authors interpreted their findings with an emphasis on the issue of suppression, and make the reasonable suggestion that failure to inhibit tics in TS may result from an impaired ability to alter subcortical neuronal activity. While they noted that the higher rate of spontaneous tics in their control condition was a possible confounding factor, they felt that this was unlikely because they expected that the higher rate of tics would produce a greater change in magnetic resonance imaging signal intensity during successful tic suppression, and correlate positively (not negatively, as observed) with severity of tic symptoms (measured outside of the scanner). However, this would not be the case in regions active during both tics.

Figure 2. Correlations in a single patient with Tourette syndrome between regional cerebral blood flow (rCBF) and scan scores for coprolalia in the left frontal operculum/inferior frontal gyrus (A), and for motor tics in the left sensorimotor cortex (B). These activated regions (thresholded at \( P < .001 \), with spatial extent corrected for multiple comparisons at \( P < .05 \)) are superimposed in color on axial slices from a stereotactically transformed structural magnetic resonance imaging template. L indicates left.
and (possibly to a different degree in) their suppression. In the current study, tics were not suppressed, and were counted and characterized during the scans and differences in numbers of tics, and possibly urge, are not an issue. The results of these 2 studies can therefore be taken together, possibly suggesting that anterior cingulate and midfrontal activity is common to both tics and their suppression, and that putamen and sensorimotor cortex (motor outflow) activity is higher during tics and lower during suppression. While the pattern of increased activity noted in the current study could be primary, it is also quite possible that it could result from failure of inhibition.

Although these statistically significant results represent a sampling of hundreds of tics in 72 images from multiple subjects, the population studied is still relatively small, the analysis applies for just this group of subjects, and further studies will be necessary to replicate, extend, and assess the generalizability of these findings. Possible medication effect in 4 of the subjects also has to be considered as a potential limitation, although a number of points make this issue less likely to affect the results: the target symptom (tics), and therefore the neural firing underlying it, was active despite medication in the 4 medicated patients (2 were unmedicated); the analysis determines the variance induced by tics in a constant pharmacodynamic/pharmacokinetic setting over the course of the study session; and subject-specific effects, including medication and dosage (chlorpromazine equivalents), were partialed out in the analysis. Despite the 2 videotapes and throat microphone, it is possible that extremely subtle tics may have been missed, although patients with known severe, stereotypical tics were studied. Regarding timing, it should be kept in mind that the temporal discrimination achieved with this technique is not due to direct temporal resolution, the timing measures were to the nearest second, possible subcomponents of tic cannot be resolved, and it is not possible to say where the activation in the identified systems begins, or whether it occurs in parallel. Future analyses and studies can examine these issues, as well as similarities and differences between subtypes of tics, within and between individual unmedicated patients.

In conclusion, activity was noted specifically during tics in motor/vocalization, paralimbic, premotor, and executive fronto-subcortical brain systems. Autonomous activity in these regions may account for the striking motor and vocal acts of TS patients, and may contribute to the “unvoluntary” experience of an irresistible urge that often accompanies these acts. Indeed, tics may represent a paradoxical state in which brain regions important for motivational aspects of behavior, and normally associated with a subjective sense of volition as they initiate action, are not operating under the volitional control of the patient. This suggested systems-level pathophysiology of TS is consistent with observations of behavioral changes associated with lesions and stimulation in medial frontal regions, and these findings may contribute to a framework for future studies.
